Covers: Scalars · Vectors · Linear Dependence/Independence · Span (Filling $\mathbb{R}^n$) · Matrix Multiplication (Coefficient/Column View) · System of Linear Equations · Rank · Gaussian Elimination

1. Scalars

A **scalar** is a single number from a field (for GATE, almost always $\mathbb{R}$ — sometimes $\mathbb{C}$ or $\mathbb{Q}$).

- Denoted by lowercase letters: $a, b, c, \lambda, k, \alpha, \beta$.
- Operations: addition, multiplication, scalar inverse (if nonzero).
- **Key role in LA:** scalars are the "weights" used to scale vectors and build linear combinations.
- **Field convention:** for GATE the scalar field is always $\mathbb{R}$ (sometimes $\mathbb{C}$ in eigenvalue questions). The field determines what counts as a "linear combination", so it can in principle change LI/LD — but you won't see this nuance in GATE.

Nuance: 0 is a scalar but also the zero of the field. Multiplying any vector by 0 gives the zero vector — this single fact is the gateway to half of linear dependence theory.

2. Vectors

2.1 Definition

A vector in $\mathbb{R}^n$ is an ordered n-tuple of real numbers:

$$\mathbf{v} = (v_1, v_2, \dots, v_n) \text{ or } \begin{bmatrix} v_1 \\ v_2 \\ \vdots \\ v_n \end{bmatrix}$$

- **Geometric view:** an arrow from origin to the point $(v_1, \dots, v_n)$. Has **magnitude + direction**.
- **Algebraic view:** an element of the vector space $\mathbb{R}^n$.
- **Column convention:** in LA we treat vectors as **column vectors** by default. Row vectors are transposes.

2.2 Core Operations

Operation	Definition	Geometric meaning
Addition	component-wise	Parallelogram / tip-to-tail
Scalar mult $c \cdot \mathbf{v}$	scale each component	Stretches when $ c > 1$, shrinks when $ c < 1$, flips when $c < 0$
Zero vector $\mathbf{0}$	all components 0	Origin
Negative $-\mathbf{v}$	$(-1) \cdot \mathbf{v}$	Same magnitude, opposite direction

2.3 Axioms a vector space must satisfy (10 axioms — memorize the gist)

Two closure axioms (closure under $+$ and under scalar $\cdot$), plus 8 algebraic axioms:

1. Commutativity of $+$: $\mathbf{u} + \mathbf{v} = \mathbf{v} + \mathbf{u}$
2. Associativity of $+$: $(\mathbf{u} + \mathbf{v}) + \mathbf{w} = \mathbf{u} + (\mathbf{v} + \mathbf{w})$
3. Additive identity: $\exists \mathbf{0}$ with $\mathbf{v} + \mathbf{0} = \mathbf{v}$
4. Additive inverse: $\exists -\mathbf{v}$ with $\mathbf{v} + (-\mathbf{v}) = \mathbf{0}$
5. Associativity of scalar mult: $a(b\mathbf{v}) = (ab)\mathbf{v}$
6. Multiplicative identity: $1 \cdot \mathbf{v} = \mathbf{v}$
7. Distributivity over vector sum: $a(\mathbf{u} + \mathbf{v}) = a\mathbf{u} + a\mathbf{v}$
8. Distributivity over scalar sum: $(a + b)\mathbf{v} = a\mathbf{v} + b\mathbf{v}$

GATE trap: If a set is missing the zero vector, it can't be a vector space / subspace. Always check $\mathbf{0} \in S$ first.

2.4 Linear Combination — the heartbeat of LA

Given vectors $\mathbf{v}_1, \dots, \mathbf{v}_k$ and scalars $c_1, \dots, c_k$:

$$\mathbf{w} = c_1\mathbf{v}_1 + c_2\mathbf{v}_2 + \dots + c_k\mathbf{v}_k$$

- Every concept ahead (span, dependence, rank, solution of $A\mathbf{x}=\mathbf{b}$) is a question **about linear combinations**.

- **Trivial combination:** all $c_i = 0 \Rightarrow$ result is 0 . This always works — it's the boring one.
- **Non-trivial combination:** at least one $c_i \neq 0$.

3. Linearly Dependent & Independent Vectors

3.1 Formal Definition

Vectors $v_1, v_2, \dots, v_k$ are **linearly independent (LI)** if:

$$c_1 v_1 + c_2 v_2 + \dots + c_k v_k = 0 \Rightarrow c_1 = c_2 = \dots = c_k = 0$$

i.e., the **only** way to combine them to get zero is the trivial way.

They are **linearly dependent (LD)** if there exists at least one **non-trivial** combination giving 0 .

3.2 Equivalent Characterizations (any of these $\Leftrightarrow$ LD)

1. Some v_i can be written as a linear combination of the others.
2. One vector is **redundant** — removing it doesn't shrink the span.
3. The matrix $[v_1 \mid v_2 \mid \dots \mid v_k]$ has rank $< k$.
4. If $k = n$ (same as dimension), $\det([v_1 \mid \dots \mid v_n]) = 0$.
5. The homogeneous system $Ax = 0$ has a **non-trivial solution**.

3.3 Quick-Fire Rules (memorize cold — these save minutes in GATE)

Situation	Status	Reason
Set contains the zero vector	LD	$1 \cdot 0 + 0 \cdot v_2 + \dots = 0$ is non-trivial
Single nonzero vector $\{v\}$	LI	$cv = 0 \Rightarrow c = 0$
Single zero vector $\{0\}$	LD	(above rule)
Two vectors, one a scalar multiple of the other	LD	$v_2 = kv_1 \Rightarrow kv_1 - v_2 = 0$
Two vectors, neither a multiple of the other	LI	—
More than n vectors in $\mathbb{R}^n$	Always LD	Can't have $> n$ LI vectors in n -dim space
Subset of LI set	LI	Independence is hereditary downward
Superset of LD set	LD	Dependence is hereditary upward
Orthogonal set of nonzero vectors	LI	Take dot product with v_i — only c_i survives

Trick: Before doing any computation, count. If you see 3 vectors in $\mathbb{R}^2$, 4 in $\mathbb{R}^3$, 5 in $\mathbb{R}^4$ — instantly **LD**. Don't compute.

3.4 How to Check LI/LD — methods ranked by speed

1. **Inspection** — multiples? zero vector? count > dim?
2. **Determinant** — only when matrix is **square** ($k = n$). $\det \neq 0 \Leftrightarrow \text{LI}$.
3. **Row reduce** $[v_1 \mid v_2 \mid \dots \mid v_k]$ to echelon form. Count pivots: - pivots = $k \Rightarrow \text{LI}$ - pivots < $k \Rightarrow \text{LD}$
4. **Solve** $Ax = 0$ — only trivial solution $\Rightarrow \text{LI}$.

3.5 Nuances often tested

- **LI** is a property of the **set**. Saying "a single vector v is **LI**" is just shorthand for " $\{v\}$ is **LI**" — which boils down to $v \neq 0$. The interesting **LI/LD** questions start at 2+ vectors.
- A set of **LI** vectors may become **LD** when you add a vector (you introduced a redundancy).
- **LI** does **not** require orthogonality. **Nonzero orthogonal set** $\Rightarrow \text{LI}$, but **LI** $\nRightarrow$ orthogonal.
- **LI/LD** is invariant under reordering of the vectors. Order doesn't matter.

4. Span — "Filling" the Space $\mathbb{R}^n$

4.1 Span Definition

$$\text{span}\{v_1, \dots, v_k\} = \{c_1 v_1 + \dots + c_k v_k : c_i \in \mathbb{R}\}$$

The set of **all possible linear combinations** of the given vectors.

4.2 What does span look like geometrically?

Vectors	Span (assuming nonzero & non-trivial)	In $\mathbb{R}^3$ it's...
1 vector	a line through origin	a line
2 LI vectors	a plane through origin	a plane
3 LI vectors	all of $\mathbb{R}^3$	the whole space
2 LD vectors	a line	a line (collapse!)

The "size" of the span is the number of **LI** vectors, not the number of vectors you started with.

4.3 When do vectors span $\mathbb{R}^n$? (the filling condition)

Vectors $v_1, \dots, v_k$ span $\mathbb{R}^n$ iff the matrix $A = [v_1 \mid \dots \mid v_k]$ has **rank n** (full row rank).

- **Need at least n vectors** to span $\mathbb{R}^n$. (Fewer $\Rightarrow$ impossible.)
- **Exactly n **LI** vectors** span $\mathbb{R}^n$ and form a **basis**.
- More than n vectors **can** span $\mathbb{R}^n$ but then they're **LD** (some are redundant).

4.4 Basis & Dimension

- **Basis** = a set that is (1) **LI** and (2) spans the space. Both conditions required.
- **Dimension** of $\mathbb{R}^n = n$. Every basis of $\mathbb{R}^n$ has exactly n vectors.
- **Standard basis** of $\mathbb{R}^n$: $e_1 = (1, 0, \dots, 0)$, $e_2 = (0, 1, 0, \dots, 0)$, ..., $e_n = (0, \dots, 0, 1)$.

4.5 Tight relationships — keep these on the tip of your tongue

For k vectors in $\mathbb{R}^n$:

- $k < n$: can be LI, but cannot span $\mathbb{R}^n$.
- $k = n$: LI $\Leftrightarrow$ spans $\mathbb{R}^n \Leftrightarrow$ basis $\Leftrightarrow \det \neq 0 \Leftrightarrow$ invertible. (The big equivalence!)
- $k > n$: spans $\mathbb{R}^n$ possible, but always LD.

GATE Tip: In any "is it a basis?" question with $k = n$, just compute the determinant. Nonzero $\Rightarrow$ basis. Done.

5. Matrix Multiplication — Coefficient (Column) View

5.1 The Four Views of AB

Let A be $m \times n$, B be $n \times p$. Then AB is $m \times p$.

View	What it says	When to use
Entry view (standard)	$(AB)_{ij} = \sum_k a_{ik} b_{kj}$ (row $\cdot$ column)	Computing single entries
Column view (coefficient view) ★	Column j of $AB = A \cdot$ (column j of B) = linear combination of columns of A with weights from column j of B	Solving $Ax = b$; understanding rank
Row view	Row i of $AB =$ (row i of A) $\cdot B$ = linear combination of rows of B with weights from row i of A	Row space arguments
Outer product view	$AB = \sum_k (\text{col}_k A)(\text{row}_k B)$ — sum of rank-1 matrices	SVD, low-rank approximations

5.2 Column View in Depth — the one you must internalize

For $Ax = b$:

$$Ax = x_1 a_1 + x_2 a_2 + \cdots + x_n a_n$$

where a_j is the j -th column of A .

Ax is a linear combination of the columns of A , with the entries of x as the coefficients.

This single reinterpretation is the most important sentence in early linear algebra. Burn it in.

Immediate consequences:

- $Ax = b$ has a solution $\Leftrightarrow b \in \text{span}\{\text{columns of } A\} = \text{column space } C(A)$.
- $Ax = 0$ has a non-trivial solution $\Leftrightarrow$ columns of A are LD.
- If columns of A span $\mathbb{R}^m$, then $Ax = b$ is solvable for every b .

5.3 Properties — keep handy

- Associative: $(AB)C = A(BC)$ ✓

- Distributive: $A(B+C) = AB + AC$ ✓
- NOT commutative: $AB \neq BA$ in general. (They may not even have compatible sizes.)
- $(AB)^T = B^T A^T$ (order flips)
- $(AB)^{-1} = B^{-1} A^{-1}$ (order flips, when both invertible)
- $AI = IA = A$
- $A \cdot 0 = 0$, but $AB = 0$ does NOT imply $A = 0$ or $B = 0$. (Zero-divisor trap.)
- $AB = AC$ does NOT imply $B = C$ in general. You can left-cancel A only when A has full column rank (left-invertible) — for square A that means A is invertible.

5.4 Size sanity check (GATE one-liners)

$A_{\{m \times n\}} \cdot B_{\{n \times p\}} = C_{\{m \times p\}}$. Inner dimensions must match. Always check this first in any matrix problem — you'll catch typos and trick questions.

6. System of Linear Equations: $Ax = b$

6.1 Two Pictures

Row picture: each equation = a hyperplane in $\mathbb{R}^n$. Solution = intersection of all hyperplanes.

Column picture: find weights $x_1, \dots, x_n$ so the columns of A combine to give b . (Column view from §5.2.)

Switch between these views fluently. The column view is what GATE tests most.

6.2 Three Cases of Solvability

Case	Condition (in terms of rank)	Geometric meaning
No solution (inconsistent)	$\text{rank}(A) \neq \text{rank}([A b])$	Hyperplanes have no common intersection; $b \notin C(A)$
Unique solution	$\text{rank}(A) = \text{rank}([A b]) = n$ (# unknowns)	Single intersection point
Infinitely many solutions	$\text{rank}(A) = \text{rank}([A b]) < n$	Intersection is a line/plane/...

Master formula (consistent case only): # free variables = $n - \text{rank}(A)$.

- 0 free variables $\Rightarrow$ unique solution.
- $k \geq 1$ free variables $\Rightarrow \infty$ solutions, parametrized by k parameters.

6.3 Homogeneous Systems: $Ax = 0$

- Always consistent — $x = 0$ is always a solution (the trivial solution).
- Has non-trivial solution $\Leftrightarrow \text{rank}(A) < n \Leftrightarrow$ columns of A are LD $\Leftrightarrow$ (if square) $\det(A) = 0$.
- Solution set is a subspace of $\mathbb{R}^n$ called the null space $N(A)$, with $\dim N(A) = n - \text{rank}(A)$ (nullity).

6.4 Non-homogeneous: $Ax = b$

- General solution = (any particular solution) + (general solution of $Ax = 0$)

$$\mathbf{x}_{\text{gen}} = \mathbf{x}_p + \mathbf{x}_h$$

- Not a subspace (doesn't pass through origin unless $\mathbf{b} = \mathbf{0}$).

6.5 Square Systems ($\mathbf{A}$ is $n \times n$) — the cleanest case

The following are equivalent:

1. $\mathbf{A}$ is invertible.
2. $\det(\mathbf{A}) \neq 0$.
3. $\text{rank}(\mathbf{A}) = n$ (full rank).
4. Columns (and rows) of $\mathbf{A}$ are LI.
5. Columns of $\mathbf{A}$ span $\mathbb{R}^n$.
6. $\mathbf{Ax} = \mathbf{0}$ has only the trivial solution.
7. $\mathbf{Ax} = \mathbf{b}$ has a unique solution $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$ for every $\mathbf{b}$.
8. 0 is not an eigenvalue.

The "Invertible Matrix Theorem" — memorize this chain. GATE recycles it constantly.

7. Rank

7.1 Definitions (all equivalent)

- Max number of linearly independent rows (row rank).
- Max number of linearly independent columns (column rank).
- Number of pivots in any echelon form of $\mathbf{A}$.
- Dimension of the row space = dimension of the column space.
- Order of the largest non-vanishing minor (determinant of submatrix).

Theorem: row rank = column rank (always). ✓ (Why we just say "rank".)

7.2 Bounds & Basic Properties

For $\mathbf{A}$ of size $m \times n$:

- $0 \leq \text{rank}(\mathbf{A}) \leq \min(m, n)$.
- $\text{rank}(\mathbf{A}) = 0 \Leftrightarrow \mathbf{A} = \mathbf{0}$ (zero matrix).
- $\text{rank}(\mathbf{A}) = \text{rank}(\mathbf{A}^T)$.
- Full row rank: $\text{rank}(\mathbf{A}) = m$. Full column rank: $\text{rank}(\mathbf{A}) = n$. Full rank (square): both at once.

7.3 Key Rank Inequalities (GATE-bait)

- $\text{rank}(\mathbf{A} + \mathbf{B}) \leq \text{rank}(\mathbf{A}) + \text{rank}(\mathbf{B})$
- $\text{rank}(\mathbf{AB}) \leq \min(\text{rank}(\mathbf{A}), \text{rank}(\mathbf{B}))$ ★ — very commonly tested
- $\text{rank}(\mathbf{AB}) \geq \text{rank}(\mathbf{A}) + \text{rank}(\mathbf{B}) - n$ (Sylvester's inequality; n = inner dim)
- If $\mathbf{A}$ is $m \times n$ of rank r , then $\text{nullity}(\mathbf{A}) = n - r$. (Rank–Nullity Theorem)
- $\text{rank}(\mathbf{A}^T \mathbf{A}) = \text{rank}(\mathbf{A} \mathbf{A}^T) = \text{rank}(\mathbf{A})$ (over $\mathbb{R}$)
- Multiplying by an invertible matrix doesn't change rank: $\text{rank}(\mathbf{PA}) = \text{rank}(\mathbf{AQ}) = \text{rank}(\mathbf{A})$ when $\mathbf{P}, \mathbf{Q}$ invertible.

7.4 How to Compute Rank

1. Row-reduce A to echelon form.
2. Count non-zero rows = number of pivots = rank.

Echelon form (not RREF) is enough — saves time. RREF only when you also need solutions.

7.5 Rank-Based Reading of $Ax = b$ (one-glance method)

Compare $r = \text{rank}(A)$ and $r' = \text{rank}([A|b])$:

Comparison	# solutions
$r \neq r'$	None (inconsistent)
$r = r' = n$	Unique
$r = r' < n$	Infinite (with $n - r$ free vars)

Always do this first before any actual solving — it tells you what to aim for.

8. Gaussian Elimination (to solve $Ax = b$)

8.1 Three Elementary Row Operations (ERO)

Symbol	Operation	Effect
$R_i \leftrightarrow R_j$	swap two rows	reorder equations
$R_i \rightarrow cR_i \ (c \neq 0)$	scale a row	multiply equation by c
$R_i \rightarrow R_i + cR_j$	add multiple of another row	linear combo of equations

EROs preserve the solution set. That's the whole point.

8.2 The Procedure

1. Form the augmented matrix $[A | b]$.
2. Forward elimination: use EROs to get row echelon form (REF): - All zero rows at the bottom. - Each leading (pivot) entry is to the right of the one above it.
3. Check consistency: - Any row of the form $[0 \ 0 \ \dots \ 0 \ | \ c]$ with $c \neq 0 \Rightarrow$ no solution. Stop.
4. Back substitution (or continue to reduced REF with leading 1's and zeros above each pivot, then read solution directly).

8.3 Echelon Form vs Reduced Echelon Form

- REF: zeros below each pivot. Useful for finding rank/consistency.
- RREF: zeros above and below each pivot, pivots are 1. Useful for writing the explicit solution.

8.4 Pivots, Basic & Free Variables

- A column with a pivot $\Rightarrow$ corresponding variable is a **basic (pivot) variable**.
- A column without a pivot $\Rightarrow$ corresponding variable is a **free variable** (parameter).
- (For consistent systems) # free variables = $n - \text{rank}(A)$.
- This same number $n - \text{rank}(A)$ is the **nullity** of A (dimension of the null space $N(A)$ = solution space of $Ax = 0$, which is always consistent).

8.5 Reading off solution from RREF (recipe)

1. If any row is $[0 \dots 0 \mid \text{nonzero}] \rightarrow$ no solution.
2. Else, assign each free variable a parameter ($t, s, \dots$).
3. Express each basic variable in terms of the free ones using its pivot row.
4. Write $x = x_p + t_1 v_1 + t_2 v_2 + \dots$ (particular + homogeneous parts).

8.6 Worked-style template (commit this pattern)

Augmented: $[A \mid b]$

$\downarrow$ forward elimination (EROs)

REF: $[U \mid c] \leftarrow$ check: any $0 \dots 0 \mid \text{nonzero}$? $\rightarrow$ No solution

$\downarrow$ back-sub (or RREF + read)

Solution: $x = x_p + \sum t_i \cdot n_i$
 $\quad \quad \quad \underbrace{\hspace{1.5cm}}_{\text{particular}} \quad \underbrace{\hspace{1.5cm}}_{\text{basis of } N(A)}$

8.7 Common Pitfalls / Tricks

- **Never** scale a row by 0 . (Invalidates the operation.)
- **Never** do $R_i \rightarrow R_i + 0 \cdot R_j$ — pointless.
- Keep one operation per step; mixing two EROs in one step is where students miscount.
- When elements get ugly (fractions), it often signals a **bad pivot order** — try a row swap.
- **Partial pivoting** (always pick the largest-magnitude entry as pivot) is a numerical tip, useful in computational questions.
- After elimination, **always sanity-check** by plugging at least one component back into one original equation.

8.8 Reading off rank, nullity, # solutions in one pass

Once you've reached REF of $[A \mid b]$:

- $\text{rank}(A)$ = pivots in the A portion.
- $\text{rank}([A|b])$ = pivots in the whole augmented matrix.
- Compare per §7.5 — instantly classify the system.

8.9 Why elimination works (the conceptual anchor)

Every ERO is equivalent to **left-multiplying** by an **invertible elementary matrix** E . So forward elimination is the composition $E_k \dots E_2 E_1 A = U$. Each E_i is invertible, so **rank** and the **solution set of $Ax = b$** are preserved.

If A is square and elimination proceeds with non-zero pivots and **no row swaps**, you've effectively factorized $A = LU$ (LU decomposition — preview for later).

9. Quick GATE Cheat-Sheet (last-minute glance)

- More vectors than dimensions $\Rightarrow$ LD. (Don't compute.)
- Square matrix: $\det = 0 \Leftrightarrow$ LD columns $\Leftrightarrow$ singular $\Leftrightarrow Ax = 0$ has non-trivial sol $\Leftrightarrow \text{rank} < n$.
- $Ax = b$ solvability: compare $\text{rank}(A)$ and $\text{rank}([A|b])$.
- # free variables = $n - \text{rank}(A)$ (for consistent systems).
- $\text{rank}(AB) \leq \min(\text{rank } A, \text{rank } B)$ — favorite trap.
- Rank doesn't change under invertible multiplications, transpose, or EROs.
- Column view of Ax : linear combination of A's columns with x's entries as weights.
- Two parallel/proportional rows in A $\Rightarrow$ rank drops by 1.
- Zero row/column $\Rightarrow$ rank loses 1.
- Standard basis $\{e_1, \dots, e_n\}$ is LI, spans $\mathbb{R}^n$, and is orthonormal.
- Homogeneous system always consistent; non-trivial iff $\text{rank} < n$.
- Determinant only defined for square matrices; rank is defined for any size.

10. Mental Models / "Why I should care"

1. Vectors = arrows you can stretch and add.
2. Linear combination = recipe for cooking new vectors out of old ones.
3. Span = pantry — everything you could cook with the ingredients you have.
4. LI = no wasted ingredients — each contributes a flavor you can't get from the others.
5. Basis = minimal complete cookbook for the space.
6. Rank = how many genuinely independent ingredients you actually have.
7. $Ax = b$: "Can I cook b using the recipes encoded by A's columns? If yes, how many ways?"
8. Gaussian elimination = simplifying the recipe until the answer is obvious — without changing what you're cooking.

End of Part 1. Up next: Determinants $\rightarrow$ Inverse $\rightarrow$ Eigenvalues/Eigenvectors $\rightarrow$ Diagonalization $\rightarrow$ LU/Cholesky $\rightarrow$ Special matrices.
